### Introduction

Microarray analysis is that the polymerase chain reaction (PCR) amplification of the cloned cDNAs of interest. We routinely use PCR amplification of cloned cDNAs using purified plasmid DNA because the template, but crude lysates also work well in providing good quality PCR products for array analysis. Nevertheless, the quality of PCR products needs to be evaluated by agarose gel electrophoresis as only successful PCR reactions with a single dominant band should be arrayed on filter membranes. Transcriptomics technologies are the techniques went to study an organism's transcriptome, the sum of all of its RNA transcripts. The information content of an organism is recorded within the DNA of its genome and expressed through transcription. Here, mRNA may be a transient intermediary molecule within the knowledge network, whilst noncoding RNAs perform additional diverse functions. A transcriptome captures a snapshot in time of the entire transcripts present during a cell. Transcriptomics and DILI prediction became evident with the pioneering studies within the early 2000's. These early studies primarily focused on rodent in vivo studies which were later shown to translate to surrogate organic phenomenon markers of DILI in human blood samples. The current challenge is to detect DILI signatures early from human in vitro cellular models. These advanced approaches for transcriptomic profiling mean that, when conducting traditional or tailored in vivo studies, the addition of satellite treatment groups specifically to gauge transcriptomics aren't necessarily needed. Nor is it necessary to concurrently conduct transcriptomic profiling with in vivo studies. For little additional cost to the study, RNA can be isolated from tissues of interest for further analysis after completion of the study. Single-cell transcriptomics has recently emerged as one of the foremost promising tools for understanding the range of the transcriptome among single cells. Image-based transcriptomics is exclusive compared to other methods because it doesn't require conversion of RNA to cDNA before signal amplification and transcript quantification. Thus, its efficiency in transcript detection is unmatched by other methods. In

addition, image-based transcriptomics allows the study of the spatial organization of the transcriptome in single cells at single-molecule, and, when combined with superresolution microscopy, nanometer resolution. Target identification using functional genomics, the identification of which genes are expressed or suppressed in diseased cells and tissues, has proven to be a strong breakthrough in genomics. Many genomics initiatives are initiated within the past decade. Cyanobacteria suffer from an equivalent product inhibition problems as people who plague other microbial biofuel hosts. High concentrations of butanol severely reduce growth, and even small amounts can negatively affect metabolic processes. A transcriptome may be a collection of RNA transcribed from a specific issue or cell at a particular developmental stage or functional state. Studies of transcriptomes could reveal gene function and gene structure, and promote our understandings on specific biological processes and molecular mechanisms. Transcriptomics within environmental physiology, it does illustrate the types of research questions that transcriptomic experiments are best suited to deal with. A wider understanding of potential limitations of transcriptomics is especially relevant given that technological advances have made transcriptomics increasingly accessible, and more and more researchers are likely contemplating integrating this technology into their research programs. I will explore the development of Robust Cell Type Decomposition (RCTD), a computational method that leverages cell type profiles learned from single-cell RNA sequencing data to decompose mixtures, like those observed in spatial transcriptomic technologies. Our RCTD approach accounts for platform effects introduced by systematic technical variability inherent to different sequencing modalities. Herbicides are the most frequently used means of controlling weeds. For many herbicides, the target site is known; however, it's considerably less clear how plant organic phenomenon changes in response to herbicide exposure. In this study, changes in gene expression in response to herbicide exposure in imazamox-sensitive (S) and-resistant (R) junglerice biotypes was examined. A major advance in NGS technology occurred with the development of paired-end (PE) sequencing. PE sequencing involves sequencing both ends of the DNA fragments in a library and aligning the forward and reverse reads as read pairs. In addition to producing twice the number of reads for the same time and energy in library preparation, sequences aligned as read pairs enable more accurate read alignment and therefore the ability to detect indels, which is not possible with single read data. Analysis of differential read-pair spacing also allows removal of PCR duplicates, a common artefact resulting from PCR amplification during library preparation.
